Abstract
This paper is focused on the computation of Answer Sets of logic programs. First of all the problem is reduced to the problem of finding a suitable coloring on directed graphs. Then the problem of finding a suitable coloring is relaxed to a combinatorial optimization problem and solved (in an approximate way) by a continuous discrete time system derived by a genetic model.

Introduction
Answer Sets Programming (ASP) is a new, emergent, type of logic programming where each solution to a problem is represented by an answer set of a function-free logic program\(^1\) encoding the problem itself. The theoretical foundation of Answer Set Programming is the Stable Models semantics of Gelfond and Lifschitz (GelLif88). The subsequent research has clarified the relationship of this semantics with existing ones in Logic Programming and nonmonotonic reasoning, and led researchers to understand how to use it for AI applications.

Several implementations now exist for ASP (also referred to as A-Prolog and SLP), and their performance is rapidly improving; among them are CCalc (McCTur97), DeReS (ChoMarTur96), DIV (ELMPS97), SLG (CheWar96) and smodels (NieSim98).

In this position paper we outline a new computational scheme for ASP which is based on

i) a reformulation of ASP in terms of particular colorings of oriented graphs and

ii) a heuristic solution to the coloring problem based on the genetic model proposed by some of these authors in (BCCG00).

The scheme above is based on several theoretical considerations that are illustrated next.

First, following the approach described by (BCDP99; Cos00), the problem of computing the answer set of a given logic program (the instance of the problem) can be reduced to the same problem for a different, normally smaller instance, called the kernel of the program.

Second, the same works propose a novel graph representation of logic programs, called Extended Dependency Graphs (EDG), which allowed us to characterize stable models of a program in terms of distinguished 2-colorings of its EDG. These colorings are called admissible.

In other words, there is a one-to-one correspondence between the answer sets of a kernel program Ker(II) and admissible 2-colorings of the related Extended Dependency Graph EDG(Ker(II)). Therefore, the ASP problem is rephrased in terms of finding particular colorings of directed graphs; this problem will be called Admissible Coloring Problem (ACP).

Since the ASP problem is NP-complete, so is ACP, hence exact solutions to ACP cannot be found in polynomial time (of course, in the worst case). Our approach, described in the rest of the paper, is to relax the problem to that of optimizing a suitable objective function (called fitness from now on).

More precisely, we try to solve ACP by means of a continuous model of computation. We propose:

1. to relax ACP to combinatorial optimization problem, by associating each instance of the problem to a suitable fitness function, so that admissible colorings are exactly global maxima of every fitness function,

2. to maximize a fitness function by using the genetic model proposed in (BCCG00). In this model, the fitness function corresponds to a discrete-time system whose attractors are local maxima of the fitness function itself.

From Answer Sets to graph coloring
In this Section we show a reduction from ASP computation to a particular type of graph coloring introduced in (BCDP99).

The first step consists in reducing the original program \(\Pi\) to a new, smaller program \(\text{Ker}(\Pi)\) which is equivalent to the original as far as existence and number of answer sets are concerned.

\(^1\)Or, via a syntactic transformation, a restricted default theory or even a\textsc{data}log\textsuperscript{\textsc{\-}} program.
By lack of space, we cannot describe kernelization in detail, since it is based on several semantics considerations, such as that saying that stable models always contain all atoms that are true.

Three features make kernelization important:

1. $\text{Ker}(\Pi)$ is obtained by applying polynomial-time algorithms, the most important one being Dix et al. rewriting system (BDF99). Therefore, in short time we are able to create a smaller instance for the same problem.

2. Kernel programs have a standard presentation, e.g. there are no facts, and no positive conditions in rule bodies. This makes their graph representation (see below) and the subsequent algorithms easier to describe and implement.

3. Each and all answer sets of $\Pi$ consists of an answer set for $\text{Ker}(\Pi)$ augmented with atoms that are either
   
   i) true w.r.t. the Well-founded semantics (WFS), and therefore part of any answer set, or
   
   ii) obtained by simple forward reasoning from the relative answer set of $\text{Ker}(\Pi)$, $W^+(\Pi)$ (true atoms under WFS) and the rules of the program. As a result, we can go back from answer sets of the kernel to those of the original program in low polynomial time.

**Theorem 1 (BCDP99)** A program $\Pi$ has a stable model if and only if $\text{Ker}(\Pi)$ does.

Now, we proceed to give a graph representation for logic programs, although in this work we will employ it only for kernel programs.

**Definition 1 (Extended dependency graph) (EDG)**

For a logic program $\Pi$, its Extended Dependency Graph $\text{EDG}(\Pi)$ is the directed finite labeled graph $(V,E,\{+,-\})$ defined below.

**V.1** For each rule in $\Pi$ there is a vertex $a_{i,k}^{(l)}$, where $a_i$ is the head of the rule and $k$ is the index of the rule in the definition of $a_i$, all $a_i$'s;

**V.2** For each atom $a$ never appearing in a head, there is a vertex simply labeled $a$;

**E.1** For each $c_j^{(l)} \in V$, there is a positive edge $\langle c_j^{(l)}, a_{i,k}^{(l)}, + \rangle$, if and only if $c_j$ appears as a positive condition in the $k$-th rule defining $a_i$, and

**E.2** For each $c_j^{(l)} \in V$, there is a negative edge $\langle c_j^{(l)}, a_{i,k}^{(l)}, - \rangle$, if and only if $c_j$ appears as a negative condition in the $k$-th rule defining $a_i$.

It is easy to check that EDGs are isomorphic to programs (BCDP99).

For a given program $\Pi$ let $(V,E) = \text{EDG}(\Pi)$, where for simplicity $V = \{1,\ldots,l\}$, we define coloring as a function $x : V \rightarrow \{0,1\}$, denoted with the characteristic vector $(x_1,\ldots,x_l)$.

**Definition 2 (Non-admissible coloring)** A coloring $x : V \rightarrow \{0,1\}$ is non-admissible for the graph $\text{EDG}(\Pi)$ if and only if

1. $\exists i x_i = 1$ and $\exists j (i,j,-) \in E$ and $x_j = 1$ (violating type 1), or
2. $\exists i x_i = 0$ and $\forall j (j,i,-) \in E$ and $x_j = 0$ (violation of type 2).

A coloring for $\text{EDG}(\Pi)$ is admissible unless it is not admissible.

**From colorings back to Answer sets**

For any interpretation $S \subseteq \Pi$, an associate coloring $\text{col}_S$ is a total function $V \rightarrow \{0,1\}$ that satisfies the conditions: $a_i \in S$ if and only if $\exists k. \text{col}_S(a_{i,k}^{(l)}) = 1$.

Clearly, more than one coloring can be associated to $S$.

**Theorem 2 (BCDP99)**

An interpretation $S$ is a stable model of $\Pi$ if and only if there is an associated coloring $\text{col}_S$ which is admissible for $\text{EDG}(\Pi)$.

**Example 1** Let us consider the following logic program:

$$p \leftarrow \text{not } a,$$
$$p \leftarrow \text{not } b,$$
$$a \leftarrow \text{not } b,$$
$$b \leftarrow \text{not } a.$$

Clearly, there are two stable models, $S_1 = \{p,a\}$ and $S_2 = \{p,b\}$. The EDG of the program has 4 vertices, i.e., $\{p,p',a,b\}$ and 4 arcs. It has two admissible colorings, i.e., $x(p) = x(b) = 1$ (everything else being mapped on 0) and $x'(p) = x'(b) = 1$ associated to $S_1$ and $S_2$, respectively.

The genetic model

Genetic algorithms are probabilistic search algorithms inspired by mechanisms of natural selection. They have received considerable attention because of their applications to several fields such as optimization, adaptive control, and others (Gol89; Hol92). By simplifying natural laws, genetic algorithms simulate reproductive processes over a population of individuals or genotypes, typically represented by binary strings of fixed length $l$, in an arbitrary environment.

The states of a simple genetic system are populations represented by multi-sets of binary words, and its evolution is obtained by applying suitable stochastic rules.

In the model presented in (BCCG00) the stochastic rules are: recombination and mutation. In the recombination, also called bit-based simulated crossover, a weighted average of the alleles of the individuals along each bit position is done; these statistics are used to produce offsprings, whose alleles in different positions are independently generated. The use of this recombination rule instead of the biologically inspired one-point crossover, seems to present advantages in the simulation efficiency and it makes the analysis easier. In the mutation random changes in the genotypes are introduced.
More formally, given an arbitrary, fixed integer $n > 0$, a population $P$ is a multi-set of $n$ elements of $\Omega$, where $\Omega = \{0, 1\}^l = \{\omega_1, \ldots, \omega_n\}$ is the class of length $l$ binary strings. The population $P$ can be represented by the "frequency vector" $F = (F_{\omega_1}, \ldots, F_{\omega_n})$, where $F_{\omega_k} = \frac{n_k}{n}$ and $n_k$ is the number of occurrences of the word $\omega_k$ in $P$.

Let the pseudo boolean function $f : \Omega \rightarrow \mathbb{N}$ be the fitness function: the evolution of the genetic system can be described by the following steps:

1. at time 0 the state of the system is the initial population $P_0$;
2. if at time $t$ the state of the system is the population $P$ (represented by $F$), then the population at time $t + 1$ is obtained by applying the following stochastic rules:

recombination:

(a) calculate the ratio

$$\phi_{kF} = \frac{E_F[x_k \cdot f]}{E_F[f]}$$

for $k = 1, l$

where $E_F$ is the expectation under the probability distribution $F$ on $\Omega$, and $x_k(\omega)$ is the function which return the $k$-th bit of the word $\omega$,

(b) generate $\{\omega_1, \ldots, \omega_n\}$ with probability $\phi_{kF}$ to obtain $1$ in position $k$, independently from $s_i$ and $k$, for $1 \leq i \leq n$ and $1 \leq k \leq l$;

mutation: flip $k$-th bit of word $\omega_{s_i}$ with probability $0 < \eta < \frac{1}{2}$ for any $1 \leq k \leq l$ and $1 \leq i \leq n$.

As it is proved in (BCCG00), in case of infinite populations the stochastic genetic system becomes a discrete time non linear deterministic system whose states are vectors $g = (g_1, \ldots, g_l) \in [0, 1]^l$, where $g_k$ is the probability to obtain a word with $1$ in position $k$.

In order to derive the dynamics of the system, consider now the fitness function $f : \Omega \rightarrow \mathbb{N}$. The function $f$ is a pseudo boolean function and therefore it can be represented by a multivariate polynomial of degree at most one in each variable defined on $[0, 1]^l$ and coincident with $f$ on $\Omega$, that is:

$$f(x_1, \ldots, x_l) = \sum_{y_1, \ldots, y_l \in \{0, 1\}} \alpha_{y_1, \ldots, y_l} x_1^{y_1} \cdots x_l^{y_l}$$

For sake of simplicity and with abuse of notation, we denote with $f$ both the function and the associated polynomial. Notice that, since $f$ is a polynomial of degree at most one in each variable, global maxima of $f$ are on elements of $[0, 1]^l$. Moreover for every $k$ ($1 \leq k \leq l$) we can rewrite $f$ as

$$f(x) = x_k b_k(x) + a_k(x),$$

where $b_k(x)$ and $a_k(x)$ are polynomials that do not depend on $x_k$ and whose variables have degree at most one. Observe that $b_k(x) = \frac{\partial}{\partial x_k} f(x)$ and $a_k(x) = f(x) - x_k b_k(x)$.

As shown in (BCCG00), in case of infinite population the genetic model can be described by the equations

$$g_k(t + 1) = g_k(t) - \frac{b_k(g(t)) + a_k(g(t))}{g_k(t)b_k(g(t)) + a_k(g(t))}(1 - 2\eta) + \eta.$$

For $\eta \approx 0$ the following result characterizes the attractor of the previous system and justifies the use of the genetic system as local optimizer of the fitness function:

**Theorem 3** Every element $x \in \Omega$ is a fixed point for the discrete time deterministic system and every attractor is an element of $\Omega$; moreover, if $b_k(x) \neq 0$ for all $k$, then $x \in \Omega$ is an attractor if and only if

$$x_k = HS(b_k(x)) \quad k = 1, \ldots, l,$$

where $HS(x) = \begin{cases} 1, & \text{if } x \geq 0; \\ 0, & \text{otherwise.} \end{cases}$

It can be proved that a good initial condition (population) is that of maximal uncertainty, i.e. $g(0) = (\frac{1}{2}, \ldots, \frac{1}{2})$. In conclusion, the algorithm GC is sketched below.

**Algorithm GC**

**Input:** A fitness function $f : \Omega \rightarrow \mathbb{N}$, mutation rate $\eta$.

for $k = 1, l$ do $G_k := \frac{1}{2}$;

while (not end cond.) do

for $k = 1, l$ do

$G_k := (1 - 2\eta)G_k \frac{b_k(G) + a_k(G)}{f(G)} + \eta$;

for $k = 1, l$ do

if $G_k \geq \frac{1}{2}$ then $X_k := 1$;

else $X_k := 0$;

**Output:** $X \in \Omega$.

**A fitness function for ACP**

In this section we define a fitness function for the ACP problem and we show how GC can be used to optimize it.

Given an extended dependency graph $G = (V, E)$, let $V = \{1, \ldots, l\}$ be the set of vertices and $E \subseteq V \times V$ the set of arcs of $G$; we said that an arc $e = (i, j)$ is incident with the vertex $j$ and write $i \rightarrow j$. Let $M = (m_{ij})_{i \times j}$ be the adjacency matrix of $G$, i.e. $m_{ij} = 1$ iff $i \rightarrow j$ otherwise $m_{ij} = 0$, and let $A = (a_{ij})_{i \times j}$ be the symmetric matrix such that $a_{ij} = 1$ iff $(i, j)$ or $(j, i)$ belong to $E$, otherwise $a_{ij} = 0$; the set of edges $(i, j)$ such that $a_{ij} = 1$ and $i < j$ is denoted by $E'$. The sets $In_i = \{j \in V : j \rightarrow i\}$ and $Out_i = \{j \in V : i \rightarrow j\}$.
\[ i \rightarrow j \] denote respectively in-neighborhood and out-neighborhood of the vertex \( i \).

We are now able to give a fitness function \( f : \{0,1\}^l \rightarrow \mathbb{N} \) whose maxima coincide with the admissible colorings for \( G \).

To do this, we introduce boolean functions which consider violations of I and II type as penalty factors, defined as follows:

- **violations of type I**: for each edge \((i,j) \in E'\) let us introduce the polynomial
  \[ g_{ij}(x_1, \ldots, x_l) = 1 - x_i x_j. \]

  It is easy to show that sufficient and necessary condition for avoiding violations of type I is:
  \[
  \sum_{(i,j) \in E'} g_{ij}(x_1, \ldots, x_l) = \sum_{i<j} a_{ij}(1 - x_i x_j) \\
  = |E'| - \sum_{i<j} a_{ij} x_i x_j \\
  = |E'|.
  \]

- **violations of type II**: for each vertex \( i \) let us introduce the polynomial
  \[ r_i(x_1, \ldots, x_l) = 1 - (1 - x_i) \prod_{j \in I} (1 - x_j), \]

  Also in this case it is easy to show that sufficient and necessary condition for avoiding violations of type II is:
  \[
  \sum_{i=1}^l r_i(x_1, \ldots, x_l) = l.
  \]

The fitness function we find is then given by the sum of the polynomials defined above:

\[
 f(x_1, \ldots, x_l) = \sum_{i=1}^l r_i(x_1, \ldots, x_l) + \sum_{(i,j) \in E'} g_{ij}(x_1, \ldots, x_l).
\]

As regards the admissibility of a given coloring we can only conclude:

**Theorem 4** A coloring \((y_1, \ldots, y_l)\) for the extended dependency graph \( G = (V, E) \) is admissible iff

\[
 f(y_1, \ldots, y_l) = \sup_{(x_1, \ldots, x_l) \in \Omega} f(x_1, \ldots, x_l) = l + |E'|,
\]

where \( l = |V| \).

To apply the genetic algorithm GC to ACP we only need to derive the \( b_k \) polynomials. For the fitness function specified above we have:

\[
 b_k(x_1, \ldots, x_l) = \prod_{j \in I_0^k} (1 - x_j) + \sum_{i \in \text{Out}_k} (1 - x_i) \prod_{j \in I_0^k \setminus \{k\}} (1 - x_j) - \sum_{j} a_{kj} x_j.
\]

**Relationship with other approaches**

For nonmonotonic reasoning, work along the lines of Kautz and Selman's WALKSAT has been carried out, among others, in the Default Logic framework \(^4\) by Saubion et al. (NSS00).

Perhaps the most similar approach is that of Blair (BDJR99) where he relaxes the ASP problem in two directions: the function associated to the logic program becomes continuous and its fixed points are studied over a continuous time domain. Vice versa, our system is discrete-time only.

**Relationship with SAT solvers**

A substantial amount of work on efficient approximation of logical decision problems focuses on solving the propositional satisfiability problem (SAT). Several solutions (WALKSAT, WSAT etc.) are available, and in principle, they could be applied to ASP by reducing it to satisfaction of a CNF formula.

Even tough we are not yet able to show enough experimental evidence to support our conjecture that direct reduction of ASP to SAT may not be a good strategy for efficient ASP computation, because the translation would not reflect the causal aspect of the logic programming ‘\( \vdash \)’ (or ‘\( \models \)’) connective as opposed to material implication ‘\( \subseteq \)'.
